The P0OLtype processor

(Version 3, September 1989)

The preparation of this report was supported in part by the National Science Foundation under grants IST-8201926 and MCS-8300984, and by the System Development Foundation. "T\TeX" is a trademark of the American Mathematical Society.
1. Introduction. The POOLtype utility program converts string pool files output by TANGLE into a slightly more symbolic format that may be useful when TANGLEd programs are being debugged.

It’s a pretty trivial routine, but people may want to try transporting this program before they get up enough courage to tackle TeX itself. The first 256 strings are treated as TeX treats them, using routines copied from TeX82.

2. POOLtype is written entirely in standard Pascal, except that it has to do some slightly system-dependent character code conversion on input and output. The input is read from pool file, and the output is written on output. If the input is erroneous, the output file will describe the error.

```pascal
program POOLtype(pool_file, output);
  label 9999;  { this labels the end of the program }
  type  \{ Types in the outer block 5 \}
    var  \{ Globals in the outer block 7 \}
  procedure initialize;  \{ this procedure gets things started properly \}
    var  \{ Local variables for initialization 6 \}
    begin  \{ Set initial values of key variables 8 \}
      end;
```

3. Here are some macros for common programming idioms.

```pascal
define incr(#) ≡ # ← # + 1  \{ increase a variable by unity \}
define decr(#) ≡ # ← # − 1  \{ decrease a variable by unity \}
define do_nothing ≡  \{ empty statement \}
```
4. The character set.  (The following material is copied verbatim from \TeX82.  Thus, the same system-dependent changes should be made to both programs.)

In order to make \TeX\ readily portable between a wide variety of computers, all of its input text is converted to an internal eight-bit code that includes standard ASCII, the "American Standard Code for Information Interchange."  This conversion is done immediately when each character is read in.  Conversely, characters are converted from ASCII to the user’s external representation just before they are output to a text file.

Such an internal code is relevant to users of \TeX\ primarily because it governs the positions of characters in the fonts.  For example, the character ‘\texttt{A}’ has ASCII code 65 = 101, and when \TeX\ typesets this letter it specifies character number 65 in the current font.  If that font actually has ‘\texttt{A}’ in a different position, \TeX\ doesn’t know what the real position is; the program that does the actual printing from \TeX’s\ device-independent files is responsible for converting from ASCII to a particular font encoding.

\TeX’s\ internal code is relevant also with respect to constants that begin with a reverse apostrophe; and it provides an index to the \texttt{\catcode}, \texttt{\mathcode}, \texttt{\uccode}, \texttt{\lccode}, and \texttt{\delcode} tables.

5. Characters of text that have been converted to \TeX’s\ internal form are said to be of type \texttt{ASCII\_code}, which is a subrange of the integers.

\begin{itemize}
\item \texttt{ASCII\_code} = 0 . . 255; \{ eight-bit numbers \}
\end{itemize}

This code is used in section 2.

6. The original Pascal compiler was designed in the late 60s, when six-bit character sets were common, so it did not make provision for lowercase letters.  Nowadays, of course, we need to deal with both capital and small letters in a convenient way, especially in a program for typesetting; so the present specification of \TeX\ has been written under the assumption that the Pascal compiler and run-time system permit the use of text files with more than 64 distinguishable characters.  More precisely, we assume that the character set contains at least the letters and symbols associated with ASCII codes 40 through 176; all of these characters are now available on most computer terminals.

Since we are dealing with more characters than were present in the first Pascal compilers, we have to decide what to call the associated data type.  Some Pascals use the original name \texttt{char} for the characters in text files, even though there now are more than 64 such characters, while other Pascals consider \texttt{char} to be a 64-element subrange of a larger data type that has some other name.

In order to accommodate this difference, we shall use the name \texttt{text\_char} to stand for the data type of the characters that are converted to and from \texttt{ASCII\_code} when they are input and output.  We shall also assume that \texttt{text\_char} consists of the elements \texttt{chr(first\_text\_char)} through \texttt{chr(last\_text\_char)}, inclusive.  The following definitions should be adjusted if necessary.

\begin{itemize}
\item \texttt{define text\_char \equiv char} \{ the data type of characters in text files \}
\item \texttt{define first\_text\_char = 0} \{ ordinal number of the smallest element of \texttt{text\_char} \}
\item \texttt{define last\_text\_char = 255} \{ ordinal number of the largest element of \texttt{text\_char} \}
\end{itemize}

\begin{itemize}
\item \texttt{i: integer;}
\end{itemize}

This code is used in section 2.

7. The \TeX\ processor converts between ASCII code and the user’s external character set by means of arrays \texttt{zord} and \texttt{xchr} that are analogous to Pascal’s \texttt{ord} and \texttt{chr} functions.

\begin{itemize}
\item \texttt{xord: array \{text\_char\} of ASCII\_code;} \{ specifies conversion of input characters \}
\item \texttt{xchr: array \{ASCII\_code\} of text\_char;} \{ specifies conversion of output characters \}
\end{itemize}

See also sections 12, 13, and 18.

This code is used in section 2.
8. Since we are assuming that our Pascal system is able to read and write the visible characters of standard ASCII (although not necessarily using the ASCII codes to represent them), the following assignment statements initialize the standard part of the \texttt{xchr} array properly, without needing any system-dependent changes. On the other hand, it is possible to implement \TeX with less complete character sets, and in such cases it will be necessary to change something here.

\[
\begin{align*}
\{ \text{Set initial values of key variables} \} & \equiv \\
\text{\texttt{xchr}[40]} & \gets \text{`\textasciitilde'}; \text{\texttt{xchr}[41]} \gets \text{`!'}; \text{\texttt{xchr}[42]} \gets \text{`"'}; \text{\texttt{xchr}[43]} \gets \text{`#'}; \text{\texttt{xchr}[44]} \gets \text{`$'}; \\
\text{\texttt{xchr}[45]} & \gets \text{`\&'}; \text{\texttt{xchr}[46]} \gets \text{`\('} ; \text{\texttt{xchr}[47]} \gets \text{`\('}; \\

\end{align*}
\]

See also sections 10, 11, and 14.

This code is used in section 2.

9. Some of the ASCII codes without visible characters have been given symbolic names in this program because they are used with a special meaning.

\begin{verbatim}
define null_code = '0'   \{ ASCII code that might disappear \}
define carriage_return = '15' \{ ASCII code used at end of line \}
define invalid_code = '177' \{ ASCII code that many systems prohibit in text files \}
\end{verbatim}
10. The ASCII code is “standard” only to a certain extent, since many computer installations have found it advantageous to have ready access to more than 94 printing characters. Appendix C of The TeXbook gives a complete specification of the intended correspondence between characters and TeX’s internal representation.

If TeX is being used on a garden-variety Pascal for which only standard ASCII codes will appear in the input and output files, it doesn’t really matter what codes are specified in $xchr[0..37]$, but the safest policy is to blank everything out by using the code shown below.

However, other settings of $xchr$ will make TeX more friendly on computers that have an extended character set, so that users can type things like ‘≠’ instead of ‘\ne’. People with extended character sets can assign codes arbitrarily, giving an $xchr$ equivalent to whatever characters the users of TeX are allowed to have in their input files. It is best to make the codes correspond to the intended interpretations as shown in Appendix C whenever possible; but this is not necessary. For example, in countries with an alphabet of more than 26 letters, it is usually best to map the additional letters into codes less than ‘40’. To get the most “permissive” character set, change ‘\␣’ on the right of these assignment statements to $chr(i)$.

\[\text{\langle Set initial values of key variables \rangle } + \equiv \]
\[\text{\quad for } i \leftarrow 0 \text{ to } 37 \text{ do } xchr[i] \leftarrow ‘\␣’; \]
\[\text{\quad for } i \leftarrow 177 \text{ to } 377 \text{ do } xchr[i] \leftarrow ‘\␣’; \]

11. The following system-independent code makes the $xord$ array contain a suitable inverse to the information in $xchr$. Note that if $xchr[i] = xchr[j]$ where $i < j < 177$, the value of $xord[xchr[i]]$ will turn out to be $j$ or more; hence, standard ASCII code numbers will be used instead of codes below ‘40’ in case there is a coincidence.

\[\text{\langle Set initial values of key variables \rangle } + \equiv \]
\[\text{\quad for } i \leftarrow \text{first\_text\_char to last\_text\_char do } xord[chr(i)] \leftarrow \text{invalid\_code}; \]
\[\text{\quad for } i \leftarrow 200 \text{ to } 377 \text{ do } xord[xchr[i]] \leftarrow i; \]
\[\text{\quad for } i \leftarrow 0 \text{ to } 176 \text{ do } xord[xchr[i]] \leftarrow i; \]
12. **String handling.** (The following material is copied from the `get_strings_started` procedure of TeX82, with slight changes.)

⟨Globals in the outer block 7⟩ +≡

\[ k, l: 0 \ldots 255; \{ \text{small indices or counters} \} \]

\[ m, n: \text{text char}; \{ \text{characters input from pool file} \} \]

\[ s: \text{integer}; \{ \text{number of strings treated so far} \} \]

13. The global variable `count` keeps track of the total number of characters in strings.

⟨Globals in the outer block 7⟩ +≡

\[ \text{count: integer}; \{ \text{how long the string pool is, so far} \} \]

14. ⟨Set initial values of key variables 8⟩ +≡

\[ \text{count} \leftarrow 0; \]

15. This is the main program, where `POOLtype` starts and ends.

```
define abort(#) ≡
    begin write_line(#); goto 9999;
    end

begin initialize;
⟨Make the first 256 strings 16⟩;
\[ s \leftarrow 256; \]
langle Read the other strings from the pool file, or give an error message and abort 19⟩;

```

```
write_line(’(’, count : 1, ’_characters_in_all.’);
```

9999: end.

16. define `lc_hex(#) ≡ l ← #;

if \( l < 10 \) then \( l \leftarrow l + "0" \) else \( l \leftarrow l - 10 + "a" \)

⟨Make the first 256 strings 16⟩ ≡

```
for \( k \leftarrow 0 \) to \( 255 \) do
    begin write(k : 3, ’; ’); l ← k;
    if ⟨Character \( k \) cannot be printed 17⟩ then
        begin write(chr[^#], chr[^#]);
        if \( k < ‘100 \) then \( l \leftarrow k + ‘100 \)
        else if \( k < ‘200 \) then \( l \leftarrow k – ‘100 \)
        else begin lc_hex\( k \mod 16 \); write(chr[l]); lc_hex\( k \mod 16 \); incr\( (count) \); end;
        count ← count + 2;
    end;
    if \( l = "" " \) then write(chr[l], chr[l])
else write(chr[l]);
    incr\( (count) \); write_line(’ “ ’);
end
```

This code is used in section 15.
17. The first 128 strings will contain 95 standard ASCII characters, and the other 33 characters will be printed in three-symbol form like \textasciitilde A unless a system-dependent change is made here. Installations that have an extended character set, where for example \texttt{chr[32]} = \texttt{\textasciitilde}, would like string \texttt{32} to be the single character \texttt{32} instead of the three characters \texttt{'136, '136, '132 (\texttt{\textasciitilde z})}. On the other hand, even people with an extended character set will want to represent string \texttt{15} by \texttt{\textasciitilde m}, since \texttt{15 is carriage\_return}; the idea is to produce visible strings instead of tabs or line-feeds or carriage-returns or bell-rings or characters that are treated anomalously in text files.

Unprintable characters of codes 128–255 are, similarly, rendered \texttt{\textasciitilde 80–\textasciitilde ff}.

The boolean expression defined here should be \texttt{true} unless \TeX{} internal code number \texttt{k} corresponds to a non-troublesome visible symbol in the local character set. An appropriate formula for the extended character set recommended in \texttt{The \TeX{}book} would, for example, be \texttt{}`k \in \mathbb{[}0, \mathbf{10} \ldots \mathbf{12}, \mathbf{14}, \mathbf{15}, \mathbf{33}, \mathbf{177} \ldots \mathbf{377}]`. If character \texttt{k} cannot be printed, and \texttt{k < 200}, then character \texttt{k + 100} or \texttt{k - 100} must be printable; moreover, ASCII codes \texttt{[41 \ldots 46, 60 \ldots 71, 141 \ldots 146, 160 \ldots 171]} must be printable. Thus, at least 80 printable characters are needed.

\texttt{Character \texttt{k} cannot be printed 17 \equiv (k < "\textasciitilde") \lor (k > "\textasciitilde")}

This code is used in section 16.

18. When the \texttt{WEB} system program called \texttt{TANGLE} processes a source file, it outputs a Pascal program and also a string pool file. The present program reads the latter file, where each string appears as a two-digit decimal length followed by the string itself, and the information is output with its associated index number. The strings are surrounded by double-quote marks; double-quotes in the string itself are repeated.

\begin{verbatim}
Globals in the outer block 7 \equiv
pool_file: packed file of text_char;  \{ the string-pool file output by \texttt{TANGLE} \}
xsum: boolean;  \{ has the check sum been found? \}
\end{verbatim}

19. \texttt{Read the other strings from the \textsc{pool} file, or give an error message and abort 19 \equiv}
reset(pool_file);  xsum \leftarrow \texttt{false};
if \texttt{eof(pool_file)} then abort(\texttt{"I\textasciitilde can\textasciitilde t\textasciitilde read\textasciitilde the\textasciitilde \textsc{pool} file."});
repeat \{Read one string, but abort if there are problems 20\};
until xsum;
if \texttt{!eof(pool_file)} then abort(\texttt{"\textasciitilde s\textasciitilde junk\textasciitilde after\textasciitilde the\textasciitilde check\textasciitilde sum"})
This code is used in section 15.
20.  (Read one string, but abort if there are problems 20) ≡

if eof(pool_file) then abort("POOL file contained no check sum");
read(pool_file, m, n);  { read two digits of string length }
if m ≠ '*' then
  begin if (xord[m] < '0') ∨ (xord[m] > '9') ∨ (xord[n] < '0') ∨ (xord[n] > '9') then
      abort("POOL line doesn’t begin with two digits");
l ← xord[m] * 10 + xord[n] - '0' * 11;  { compute the length }
write(s: 3, ": "); count ← count + l;
for k ← 1 to l do
      begin if coln(pool_file) then
          begin write ln(" "); abort("That POOL line was too short");
          end;
      read(pool_file, m); write(xchr[xord[m]]);
      if xord[m] = "" then write(xchr[" "]);
      end;
  end
else xsum ← true;
read ln(pool_file)

This code is used in section 19.
21. **System-dependent changes.** This section should be replaced, if necessary, by changes to the program that are necessary to make **POOLtype** work at a particular installation. It is usually best to design your change file so that all changes to previous sections preserve the section numbering; then everybody’s version will be consistent with the printed program. More extensive changes, which introduce new sections, can be inserted here; then only the index itself will get a new section number.
22. Index. Indications of system dependencies appear here together with the section numbers where each identifier is used.
